Modular algorithms for Gross–Stark units and Stark–Heegner points

Håvard Damm-Johnsen

Abstract. In recent work, Darmon, Pozzi and Vonk explicitly construct a modular form whose spectral coefficients are $p$-adic logarithms of Gross–Stark units and Stark–Heegner points. Here we describe how this construction gives rise to a practical algorithm for explicitly computing these logarithms to specified precision, and how to recover the exact values of the Gross–Stark units and Stark–Heegner points from them.

Key tools are overconvergent modular forms, reduction theory of quadratic forms and Newton polygons. As an application, we tabulate Gross–Stark units in narrow Hilbert class fields of real quadratic fields with discriminants up to 10000, for primes less than 20, as well as Stark–Heegner points on elliptic curves.

1. Introduction

The classical theory of complex multiplication, developed by Kronecker, Weber, Fueter, Deuring, Shimura and others, gives an explicit description of abelian extensions of imaginary quadratic fields $K$. They are generated by elliptic units, which are canonical units in class fields of $K$. In [Sta80], Stark proved that logarithms of elliptic units appear as the value of derivatives of Hecke $L$-functions at $s = 0$, and conjectured the existence of units over arbitrary base fields, so-called Stark units. Heegner and Birch used CM theory to construct points on modular curves, called Heegner points, also defined over class fields of $K$. By determining the heights of their images on elliptic curves, Gross and Zagier [GZ86] made an important contribution towards the Birch–Swinnerton-Dyer conjecture.

The author is supported by a scholarship from the Aker Scholarship foundation.
Let $F$ be a real quadratic field and $p$ a rational prime. While there is no direct analogue of the construction of elliptic units over $F$, Gross [Gro81] constructed what are now known as Gross--Stark units, formal powers of $p$-units in class fields of $F$, and formulated a $p$-adic analogue of Stark’s conjectures for these. His conjecture related the value of derivatives of $p$-adic $L$-functions at $s = 0$ to local norms of Gross--Stark units, which was proved in [DDP11]. This was refined to a statement with norms removed in [DKV18], and recently Dasgupta and Kakde proved an integral version where formal units are replaced with proper units [DK23].

The computation of Gross--Stark units over real quadratic fields was studied in [TY13] when $p$ splits in $F$, and [FL22] for $p$ inert in $F$. In the real-analytic setting, in [CR00] Cohen and Roblot used Stark’s conjectures to compute wide Hilbert class fields of real quadratic fields, and similar algorithms form the basis for general algorithms to compute ray class fields in pari/GP.

By analogy with Heegner points, Darmon’s work [Dar01] uses $p$-adic analysis to construct points on elliptic curves. These so-called Stark--Heegner points are conjectured to be defined over ring class fields of $F$. While this conjecture is still wide open in general, it is supported by extensive computational evidence. Efficient algorithms for computing Stark--Heegner points were first introduced in [DG02] and [DP06]. Since then, the literature on algorithmic aspects of Stark--Heegner points has expanded rapidly, a selection of which is [Gre09, GM13, GM14, GMS15, GM15].

In [DV21], Darmon and Vonk introduce rigid meromorphic cocycles which take the $p$-adic theory beyond Stark’s conjectures. Their framework gives an analogue of singular moduli for real quadratic fields, for which the techniques in this paper are expected to generalise. As a by-product, they recover a common framework for Stark units and Stark–Heegner points: in subsequent work, Darmon, Pozzi and Vonk [DPV23] use $p$-adic families of Hilbert modular forms to give an explicitly computable modular form whose spectral expansion encodes both Gross–Stark units and Stark–Heegner points.

More specifically, the authors construct a classical modular form $G$ from a parallel weight $1$ Hilbert Eisenstein series $E_{1,1}$ over a real quadratic field $F$ in which $p$ is inert. First, they define the anti-parallel weight deformation of $E_{1,1}$, and modify by a linear combination of Eisenstein families. Then they restrict the argument to the diagonally embedded upper half plane $\mathfrak{h}$ in $\mathfrak{h} \times \mathfrak{h}$, and differentiate with respect to the weight. This is shown to be a $p$-adic modular form, to which they finally apply Hida’s ordinary projector to get the modular form $G \in M_2(\Gamma_0(p))$. They also prove that the form is non-trivial when $F$ has no unit of negative norm.

A straightforward consequence of the theorems in [DPV23] is the following:

**Theorem 1.1.** Suppose $F$ has no unit of negative norm. Then

$$\langle G, f \rangle_{\Gamma_0(p)} = \begin{cases} \frac{1}{p-1} \log_p u & \text{if } f = E_2^{(p)}, \\ L_{\text{alg}}(1, f) \log_{E_f} P_f & \text{if } f \text{ is a cuspidal eigenform with coefficients in } \mathbb{Q}. \end{cases}$$

Here $u$ is a Gross–Stark unit, $E_2^{(p)}$ the Eisenstein series on $M_2(\Gamma_0(p))$, and $L_{\text{alg}}(1, f)$ the algebraic part of the special value $L(1, f)$ of the $L$-function attached to $f$. $E_f$ is the elliptic curve associated to $f$ via the Eichler–Shimura construction, $\log_{E_f}$ the formal logarithm on $E_f$, and $P_f$ a Stark–Heegner point on $E_f$, conjecturally defined over the narrow Hilbert class field of $F$. A more precise statement may be found in Theorem 2.2.
The goal of this paper is to show that the steps defining $G$ can be made completely explicit in a computer algebra system such as sage [The22] or magma [BCP97], and in particular we can compute the spectral coefficients of $G$ to arbitrary precision. A key tool is algorithms for overconvergent modular forms due to Laud 

\cite{Lau11, Lau14}, with necessary modifications for $p \in \{2, 3\}$ from \cite{Von15}. As a proof of concept, we compute tables of Gross–Stark units over $\mathbb{Q}(\sqrt{D})$ for fundamental discriminants $D < 10000$ and $p < 20$, and Stark–Heegner points on elliptic curves for $D < 100$, $p < 20$. This can be viewed as a numerical verification of the aforementioned conjecture stated in \cite{DV22}. For $p$ equal to 2 or 3, these tables are virtually complete, with only a handful of omissions due to the large height of the polynomials.

**Example 1.2.** Let $D = 8441 = 23 \cdot 367$. Then $F := \mathbb{Q}(\sqrt{D})$ has narrow class number 26, and combining Algorithm 2 and Algorithm 5 gives the polynomial

\[
3^{41}x^{26} - 3^{28} \cdot 47400593x^{25} + 3^{21} \cdot 141321377697x^{24} - 3^{14} \cdot 1491793680346193x^{23} + 3^{11} \cdot 481030589755883121x^{22} - 3^{8} \cdot 1176957019953501830x^{21} + 3^{5} \cdot 841442767734656470x^{20} - 3^{6} \cdot 5230173358710191479x^{19} + 3^{3} \cdot 1983729129037937219x^{18} - 3^{5} \cdot 28800297384178354201x^{17} + 3^{6} \cdot 13798304822142405250x^{16} - 3^{2} \cdot 131401208998818663625x^{15} + 3^{2} \cdot 1350085297035065778356x^{14} - 1207461049660929030725x^{13} + 3^{2} \cdot 1350085297035065778356x^{12} - 3^{2} \cdot 131401208998818663625x^{11} + 3^{6} \cdot 13798304822142405250x^{10} - 3^{5} \cdot 28800297384178354201x^{9} + 3^{3} \cdot 1983729129037937219x^{8} - 3^{6} \cdot 5230173358710191479x^{7} + 3^{8} \cdot 841442767734656470x^{6} - 3^{6} \cdot 1176957019953501830x^{5} + 3^{11} \cdot 481030589755883121x^{4} - 3^{14} \cdot 1491793680346193x^{3} + 3^{21} \cdot 141321377697x^{2} - 3^{38} \cdot 47400593x + 3^{43}.
\]

(1.1)

The roots of this polynomial are 3-units generating the narrow Hilbert class field of $F$, a degree 52 extension of $\mathbb{Q}$, and their square roots are Gross–Stark units attached to narrow ideal classes in $F$, as defined in Section 3.

**Example 1.3.** Let $p = 11$ and consider $E : y^2 + y = x^3 - x^2 - 10x - 20$, a model for $X_0(11)$. Using Algorithm 6 we find the points on $E$ described in Table 1. For each row, the polynomials in columns $X$ and $Y$ are the minimal polynomials of the $x$- and

y-coordinates, respectively, of a Stark–Heegner point on $E$ defined over the narrow Hilbert class field of $\mathbb{Q}(\sqrt{D})$. This field is generated over $\mathbb{Q}(\sqrt{D})$ by a root of the polynomial $P$ in the final column. For example, for $D = 24$, $(2\sqrt{-2}, 5 + 4\sqrt{-2})$ is a Stark–Heegner point on $X_0(11)$ defined over $\mathbb{Q}(\sqrt{24}, \sqrt{-2})$, which is the splitting field over $\mathbb{Q}(\sqrt{24})$ of $11x^2 - 14x + 11$.

Our paper is structured as follows: in Section 2 we first give a precise definition of Gross–Stark units and describe properties of Stark–Heegner points, then discuss the results of [DPV23] and explain how to use the classical reduction theory of indefinite binary quadratic forms to greatly improve the efficiency of the resulting algorithms. Next, in Section 3 we use the Brumer–Stark conjecture to recover a Gross–Stark unit from its $p$-adic logarithm, and describe how to compute a Stark–Heegner point from its formal logarithm. We also discuss how to verify the correctness of the data computed. Finally, we present data computed and make some observations.

The algorithms in our paper are implemented in both magma and sage, and can be found in the repositories https://github.com/havarddj/drd and https://github.com/havarddj/hilbert-eisenstein

Acknowledgements: I am very grateful to Jan Vonk for suggesting the problem and for continued guidance and suggestions, and to James Newton for helpful conversations and comments on the paper. Thanks to Alex Braat for suggesting the statement of Lemma [3.9] Samuel Frengley for help with magma, and to Alex Horawa and George Robinson for enlightening conversations. Finally, I am grateful to the anonymous reviewers who provided a large number of comments improving the content, language and exposition of the article.

2. The modular algorithm

2.1. Notation. For the remainder of the paper, $F$ will denote a real quadratic extension of $\mathbb{Q}$ of discriminant $D$, and $\mathcal{O}_F$ its ring of integers. Its different ideal, which is principal and generated by $\sqrt{D}$, will be denoted $\frak{d}$. If $\alpha \in F$, let $\alpha'$ be its conjugate.

We let $\text{Cl}^+$ be the narrow Hilbert class group of $F$, so that $\text{Cl}^+ \cong G := \text{Gal}(H/F)$ where $H$ is the narrow Hilbert class field of $F$, the maximal abelian extension of $F$ unramified at all finite places, of degree $h^+$. For $\sigma \in G$, the corresponding class in $\text{Cl}^+$ is denoted $A_\sigma$, and conversely a class $A$ in $\text{Cl}^+$ determines an automorphism $\sigma_A \in G$. The narrow ideal class group is strictly larger than the wide ideal class group if and only if $F$ has no units of norm $-1$, and in light of Theorem [1.1] we restrict our attention to this case. Under this assumption, the principal ideal $\frak{d}$ defines an element of order 2 in $\text{Cl}^+$. Furthermore, $H$ is a CM extension of the wide Hilbert class field, and the automorphism $\kappa = \sigma_\frak{d}$ plays the role of complex conjugation in $G$. We frequently write $\bar{\alpha}$ instead of $\kappa(\alpha)$ if the meaning is clear from the context.

Let $p$ be a rational prime inert in $F$. Then $p$ splits completely in $H$, and we fix a prime $\frak{P}$ of $H$ above $p$. This determines an isomorphism of completions $F_p \cong H_\frak{P}$. A function $f : \text{Cl}^+ \to \mathbb{C}$ is odd if $f(A[\frak{d}]) = -f(A)$ for all $A \in \text{Cl}^+$. The field generated by the values of a character $\psi$ is denoted by $\mathbb{Q}(\psi)$.

We say an element $\alpha \in F$ is totally positive if $\rho(\alpha) > 0$ for all embeddings $\rho : F \to \mathbb{R}$, and we write $\alpha \gg 0$. If $X \subset F$ is any subset, we set $X_+ := \{\alpha \in X : \alpha \gg 0\}$.
Given an integral ideal \( \mathfrak{a} \) of \( F \), let \( N(\mathfrak{a}) := \#(\mathcal{O}_F/\mathfrak{a}) \), and this extends to fractional ideals by \( N(\mathfrak{a}/\mathfrak{b}) := N(\mathfrak{a})/N(\mathfrak{b}) \), and to elements \( \alpha \in F^* \) by \( N(\alpha) = N((\alpha)) \), where \( (\alpha) \) denotes the fractional ideal generated by \( \alpha \). By convention, we also set \( N(x) = x^2 \) when \( x \) is an indeterminate. For any number field \( K \), \( \mu(K) \) denotes the set of all roots of unity in \( K \).

If \( \mathfrak{P} \) is a non-zero prime ideal of \( H \) and \( \alpha \in H^* \), then we set \( |\alpha|_{\mathfrak{P}} = N(\mathfrak{P})^{-\ord_{\mathfrak{P}} \alpha} \), where \( \ord_{\mathfrak{P}} \alpha \) denotes the power of \( \mathfrak{P} \) appearing in the prime ideal factorisation of \((\alpha)\). This is the so-called normalised absolute value with respect to \( \mathfrak{P} \), and in particular \( N(\mathfrak{P}) = p^2 \) in the present setting. All of our absolute values will be normalised, and we refer to [Gro81, p. 980] for a general definition which applies to both the finite and infinite places of \( H \).

The \( p \)-units in \( H \) is the group \( \mathcal{O}_H[1/p]^* := \{\alpha \in H^* : |\alpha|_v = 1 \text{ if } v \mid p\} \), where \( v \) runs over all places of \( H \). In particular, \( \alpha \in \mathcal{O}_H[1/p]^* \) has absolute value \( 1 \) under every embedding \( H \rightarrow \mathbb{C} \). This is a finitely generated abelian group by a version of Dedekind’s unit theorem, [NS13 Cor. 11.7].

### 2.2. Gross-Stark units and Stark–Heegner points.

Gross [Gro81, Prop. 3.8] proved the existence and uniqueness of a “formal power of a \( p \)-unit” \( u \in \mathcal{O}_H[1/p]^* \otimes \mathbb{Q} \) characterised by the properties

\[
\ord_{\mathfrak{P}} \sigma(u) = \zeta(0, \mathcal{A}_\sigma) \text{ for all } \sigma \in G \text{ and } \bar{u} = 1/u,
\]

where the bar denotes complex conjugation, and \( \zeta(s, \mathcal{A}_\sigma) \) is the partial \( L \)-function defined by the Dirichlet series \( \zeta(s, \mathcal{A}_\sigma) = \sum_{\alpha \in \mathcal{O}_F, |\alpha|_v = A_v} N(\alpha)^{-s} \), which admits a meromorphic continuation to \( \mathbb{C} \) in the usual manner. This depends only on the choice of prime \( \mathfrak{P} \) of \( H \) above \( p \). In [DPV23 Eq. (4)], the authors twist by elements of \( G \) to get units \( u_{\mathcal{A}} := \sigma_\mathcal{A}(\bar{u}) \) indexed by \( \mathcal{A} \in \text{Cl}^+ \), equal to \( u_\tau \) when \( \mathcal{A} = [\mathbb{Z} + \tau \mathbb{Z}] \). It is therefore characterised by

\[
\ord_{\mathfrak{P}}^\mathcal{A} u_{\mathcal{A}} = -\zeta(0, A\mathcal{A}_{\sigma^{-1}}) \text{ for all } \sigma \in G \text{ and } \bar{u}_{\mathcal{A}} = 1/u_{\mathcal{A}}.
\]

This is referred to as the Gross–Stark unit attached to \( \mathcal{A} \). Note that these are all \( G \)-conjugate: \( \sigma(u_{\mathcal{A}}) = u_{\mathcal{A} A_{\sigma}} \).

The Brumer–Stark conjecture, proven up to powers of 2 in [DK23], implies that \( u_{\mathcal{A}}^2 \), where \( e = \#\mu(H) \), gives an element of \( \mathcal{O}_H[1/p]^* \). More precisely, there exists an element \( \epsilon \in \mathcal{O}_H[1/p]^* \) satisfying \( \epsilon \otimes 1 = e \cdot u \) such that \( H(\sqrt[\mathcal{A}]{\epsilon})/F \) is an abelian extension. We set \( \epsilon_\mathcal{A} := \sigma_\mathcal{A}(\epsilon) \), which we refer to as the Brumer–Stark unit attached to \( \mathcal{A} \). These are the units we compute in Section 3.

An immediate consequence of the second part of Equation (2.2) is that \( \epsilon_\mathcal{A} \) lies on the unit circle under any embedding \( H \rightarrow \mathbb{C} \). For the remainder of the paper, we will assume the full Brumer–Stark conjecture. Our computations can then be viewed as a verification of the conjecture.

We also attach a Gross–Stark unit to a character \( \psi : G \rightarrow \mathbb{C}^* \) by setting

\[
\psi(\mathcal{A}) := \prod_{\mathcal{A} \in \text{Cl}^+} u_{\mathcal{A}}^{\psi(\mathcal{A})} = \prod_{\sigma \in G} \sigma(\bar{u})^{\psi(\mathcal{A}_{\sigma^{-1}})},
\]

which lies in \( \mathcal{O}_H[1/p]^* \otimes \mathbb{Q}(\psi) \), and satisfies \( \ord_{\mathfrak{P}} u_{\psi} = -L(0, \psi) \) and \( \sigma(u_{\psi}) = \bar{\psi}(\mathcal{A}_{\sigma^{-1}})u_{\psi} \) for all \( \sigma \in G \). This is compatible with the notation in [DDP11].

---

1However, it is different from the formula in [DPV23 Eq. (51)], in which \( u_\psi \) depends on \( \tau \), and the corresponding formula for \( \ord_{\mathfrak{P}} u_\psi \) in the proof of Lemma 3.5 is off by a factor of \( \psi(\mathcal{A}_{\sigma}) \), or \( \psi(\tau) \) in their notation.
Stark–Heegner points \( P_{\psi,f} \) are defined in [Dar01] and [Das05], and for brevity we give a description of their properties instead of a strict definition. They are defined on the modular Jacobian \( J_0(p) \), which is an elliptic curve when the genus of \( X_0(p) \) is one. More generally, if \( J_0(p) \) splits into a product of abelian varieties of which one is an elliptic curve \( E \), then there exists a cuspidal eigenform \( f \in S_2(\Gamma_0(p)) \) such that \( E \) is isogenous to \( E_f \), and \( P_{\psi,f} \) gives a point on these. The reader can find further details in [DV22 §3.7].

Pick an elliptic curve \( E_f \) in the isogeny class. In this setting, \( P_{\psi,f} \) comes from an element of \( F_p \) defined via \( p \)-adic analytic methods. By [Sil09 Thm. 14.1], \( E_f(F_p) \) is isomorphic to \( F_p^\times / q^2 \) where \( q \) is the Tate parameter attached to \( E_f \). We can find an explicit isomorphism \( E_f(F_p) \to F_p^\times / q^2 \) as follows: first find an isomorphism between \( E_f \) and the corresponding Tate curve \( E_q \) by computing their Weierstraß equations and using the command \texttt{IsIsomorphic} in \texttt{magma}. Then compute the isomorphism \( E_q \to F_p^\times / q^2 \) using the formulae in [Sil09 §C.14]. This gives a point \( P_{\psi,f} \) in \( E_f(F_p) \). However, it is conjectured in [Dar01] that it is actually defined over \( H \) via the embedding \( H \hookrightarrow H_\Q \cong F_p \), and in Section 3.2 we verify this computationally.

2.3. Diagonal restriction derivatives. Let \( \psi \) be an odd character on \( \Cl^+ \). Following [DPV23] we consider the Hilbert modular Eisenstein series \( E_{1,1}(\psi) \) of parallel weight 1 whose \( q \)-expansion at the cusp \( \mathfrak{d} \) is given by the series

\[
E_{1,1}(\psi)_\mathfrak{d} = \sum_{\nu \in \mathfrak{d}_{+}^{-1}} \sigma_{0,\psi}(\nu \mathfrak{d}) q^{\nu \mathfrak{d}},
\]

where \( \sigma_{0,\psi}(\nu \mathfrak{d}) \) is the divisor sum

\[
\sigma_{0,\psi}(\nu \mathfrak{d}) := \sum_{\mathfrak{a} | \nu \mathfrak{d}} \psi(\mathfrak{a}).
\]

For \( p \) a rational prime inert in \( F \), we also define the \( p \)-stabilisation of \( E_{1,1}(\psi) \) by \( E_{1,1}^{(p)}(\psi)(z_1, z_2) := E_{1,1}(\psi)(z_1, z_2) - pE_{1,1}(\psi)(pz_1, pz_2) \). There is a certain \( p \)-adic family of modular forms \( \mathcal{F}^+ \), a linear combination of two Eisenstein families along with the anti-parallel weight deformation, whose weight 1 specialisation equals \( E_{1,1}^{(p)}(\psi) \). Note that \( \mathcal{F}^+ \) is different from the parallel weight Eisenstein family used in [DPV21], and computing its \( q \)-expansion requires a fairly delicate argument using Galois deformation theory, the details of which are in [DPV23 §3]. Since \( E_{1,1}^{(p)}(\psi)(z, z) \) is a classical modular form of level 1 and weight 2 and therefore identically 0, \( E_{1,1}^{(p)}(\psi) \) vanishes along the diagonally embedded copy of \( \mathfrak{h} \times \mathfrak{h} \) in its domain \( \mathfrak{h} \times \mathfrak{h} \). Taking the derivative of \( \mathcal{F}^+ \) in the weight space and restricting to weight 1 then gives an overconvergent modular form in one variable, denoted by \( \partial f^+_\psi \). We refer to this as the diagonal restriction derivative, and its \( q \)-expansion is given as follows:

**Proposition 2.1 ([DPV23 Prop. 4.6]).** The diagonal restriction derivative is an overconvergent modular form of weight 2 and tame level 1 with \( q \)-expansion

\[
\partial f^+_\psi(q) = \frac{1}{2} \log_p(u_\psi) - \sum_{n=1}^{\infty} \sum_{\nu \in \mathfrak{d}_{+}^{-1}} \sum_{\substack{\mathfrak{a} \mid \nu \mathfrak{d} \tr \nu = n \tr a(n) = 1 \mathfrak{a} \mid \mathfrak{d}}} \psi(\mathfrak{a}) \log_p \left( \frac{\nu \sqrt{D}}{N(\mathfrak{a})} \right) q^{\nu}.
\]
It has rate of overconvergence \( r \) for each \( r < p/(p+1) \).

The symbol \( \log_p \) denotes the \( p \)-adic logarithm, defined by the power series
\[
\log_p(1 - x) = \sum_{n=1}^{\infty} x^n/n \text{ on its domain of convergence in } \mathcal{O}_{F_p},
\]
and extended by setting \( \log_p(p) = \log_p(\zeta) = 0 \) for any root of unity \( \zeta \) in \( F_p \). To evaluate this at elements of \( F \), we identify \( F \) with its image in \( F_p \).

Applying Hida’s ordinary projection operator \( e_{ord} \) to \( \partial f^+_\psi \) gives a classical modular form of level \( \Gamma_0(p) \) and weight 2. The space of such forms is spanned by the Eisenstein series
\[
E_2^{(p)}(z) = \frac{p-1}{24} + \sum_{n=1}^{\infty} \left( \sum_{d|n, (d,p)=1} d \right) q^n,
\]
along with eigenforms \( f \), which we normalise so that \( a_1(f) = 1 \) in the \( q \)-expansion at \( \infty \).

**Theorem 2.2.** Set \( F = \mathbb{Q}(\sqrt{D}) \) and let \( p \) be a prime inert in \( F \). Write
\[
e_{ord}(\partial f^+_\psi) = \lambda_0 E_2^{(p)} + \sum_f \lambda_f f, \text{ where } \lambda_0, \lambda_f \in F_p.
\]

Then \( \lambda_0 = \frac{1}{p-1} \log u_\psi \), and if \( a_n(f) \in \mathbb{Q} \) for all \( n \), then \( \lambda_f = L_{alg}(1,f) \log F_f(P_{\psi,f}) \), where \( P_{\psi,f} \) is a Stark–Heegner point in \( E_f(\mathbb{C}_p) \), the elliptic curve attached to \( f \) by the Eichler–Shimura construction, and \( L_{alg}(1,f) \) is the algebraic part of the value \( L(1,f) \).

Conjecture 3.19 in [DV22] states that the points \( P_{\psi,f} \) are in fact algebraic, defined over the narrow Hilbert class field of \( F \).

**Proof of Theorem 2.2.** By [DPV23, Prop. 4.7], \( G := e_{ord}(\partial f^+_\psi) \) can be written as a generating series
\[
2G(z) = \log_p(u_\psi) + \sum_{n=1}^{\infty} \log_p(T_n J_w[\psi]) q^n.
\]

Meanwhile, by [DPV23, eq. 29] the cocycle \( J_w \) decomposes as follows:
\[
J_w = \frac{2}{p-1} J_{\text{DR}} + 2 \sum_f L_{alg}(1,f) J_f^\circ \bmod J_{\text{univ}}^\circ.
\]

Plugging the expression for \( J_w \) into the \( n \)-th Fourier coefficient for \( n \geq 1 \) coprime to \( p \), we obtain
\[
a_n(G) = \frac{2}{p-1} \log_p T_n J_{\text{DR}}[\psi] + 2 \sum_f L_{alg}(1,f) \log_p T_n J_f[\psi]
\]
and
\[
(2.11 b) \quad a_n(G) = \frac{2}{p-1} \log_p (J_{\text{DR}}[\psi]) \cdot a_n(E_2^{(p)}) + \sum_f L_{alg}(1,f) \log_p (J_f[\psi]) \cdot a_n(f).
\]

Theorem B of [DPV23] combined with the proof of Theorem 4.8 in the same paper implies that \( J_{\text{DR}}[\psi] = u_\psi^{24} \), and conjecture 3.19 in [DV22] implies that \( J_f[\psi] \) maps

\[2\text{There is a sign missing in the proof of Thm. 4.8 which propagates back to Prop. 4.7. As written, the constant term of the Eisenstein series in the spectral expansion is off by a factor of } -1. \text{ We assume here that the statement of Thm. 4.8 is correct as written.}\]
to \( P_{\psi,f} \in E_f(F_p) \) under the Tate uniformisation. Denoting the composite of the Tate map and \( \log_p \) by \( \log_{E_f} \), we get that

\[
(2.12) \quad a_n(G) = \frac{24}{p - 1} \log_p(u_\psi) \cdot a_n(E_2^p) + \sum_f L_{\text{alg}}(1, f) \log_{E_f} P_{\psi,f} \cdot a_n(f).
\]

As in the proof of [DPV23 Prop. 4.7], there exists a modular form in \( M_2(\Gamma_0(p)) \) with prime to \( p \) coefficients \( a_n(G) \), which we denote by \( g \). Now \( g - G \) is an oldform in \( M_2(\Gamma_0(p)) \) as all its coefficients of index coprime to \( p \) vanish, hence equals 0, and this completes the proof. \( \square \)

This construction can be made completely explicit in a computer algebra system such as magma or sage, at least to finite \( p \)-adic precision:

1. Compute the terms \( \{ a_n \}_{n=1}^N \) of the \( q \)-expansion of \( \partial f_\psi^+ \) in Equation (2.6) up to a certain bound \( M \) by enumerating the elements \( \nu \in \mathfrak{d}_+^{-1} \) of trace \( n \) and factorising \( \nu \phi \). Since \( \log_p(x y) = \log_p x + \log_p y \) for any \( x, y \in F_p \), we only need to evaluate this once per \( n \).

3. Solve for \( \partial f_\psi^+ \) and its constant term in this basis.

4. Compute the ordinary projection as a matrix on the basis, and apply to the vector defining \( \partial f_\psi^+ \) to get \( e_{\text{ord}}(\partial f_\psi^+) \). This is described in detail in step (6) of [Lau14 Alg. 2.1].

5. Solve for \( e_{\text{ord}}(\partial f_\psi^+) \) in an eigenbasis of \( M_2(\Gamma_0(p)) \), which can be found explicitly using built-in methods in sage and magma.

In practice, the first step is very slow due to the cost of evaluating \( \psi(a) \) for many \( a \). Moreover, the coefficients of \( \partial f_\psi^+ \) lie in an extension of \( F_p \) generated by the values of \( \psi \), which is of high degree if the narrow class number of \( F \) is large.

### 2.4. Improvements using quadratic forms.

To get around these difficulties, we combine two observations: the first is that if we split the sum into a sum over classes \( A \in \text{Cl}^+ \), then it suffices to compute sums corresponding to all pairs \( (\nu, a) \) where \( a \mid \nu \phi \) and \( a \) has class \( A \) in the narrow class group, which lie in \( F_p \). The second is that by the correspondence between ideals of \( \mathbb{Q}(\sqrt{D}) \) and indefinite binary quadratic forms of discriminant \( D \), we can use reduction theory to enumerate all such ideals.

**Proposition 2.3 (Cox11 Ex. 7.21)).** There is a map between ideals of \( \mathbb{Q}(\sqrt{D}) \) and indefinite binary quadratic forms of discriminant \( D \), induced by the map

\[
(2.13) \quad a = \alpha \mathbb{Z} + \beta \mathbb{Z} \mapsto \frac{N(\alpha x - \beta y)}{N(\alpha)},
\]

This map respects the class group structure: two ideals are in the same narrow ideal class if and only if the corresponding quadratic forms are equivalent under the action of \( \text{SL}_2(\mathbb{Z}) \),

\[
(2.14) \quad \left( \begin{array}{cc} r & s \\ t & u \end{array} \right) \cdot Q = Q(rx + sy, tx + uy).
\]

We say that an indefinite quadratic form \( Q(x, y) = ax^2 + bxy + cy^2 \) is **reduced** if \( |\sqrt{D} - 2|a| < b < \sqrt{D} \). Any given form is equivalent to at most finitely many reduced forms.
Proposition 2.4. Let $F = \mathbb{Q}(\sqrt{D})$ be a real quadratic field and $A \in \text{Cl}^+$ a fixed class with associated reduced quadratic form $Q_0$. Then there is a bijection between

$$\mathfrak{I}(n, A) := \left\{ (a, \nu) : \nu \in \mathbb{Z}_+^{-1}, \text{tr} \nu = n \right\}$$

and

$$M(n, A) := \left\{ (Q = ax^2 + bxy + cy^2, \gamma) : \gamma \in N_n, \; Q \sim Q_0^\gamma,\; a > 0 > c \right\},$$

where $N_n$ is a set of double coset representatives of

$$\text{SL}_2(\mathbb{Z}) \setminus \{ \gamma \in \text{Mat}_2(\mathbb{Z}) : \det \gamma = n \}/\text{Stab}_{\text{SL}_2(\mathbb{Z})}(Q_0).$$

Proof. This is essentially [LV22, Lemma 4.1], except we identify $\tau$ with its associated quadratic form. \hfill \Box

We call an element $Q \in M(n, A)$ a nearly reduced form since although it might not be reduced in the strict sense, it is an element of the reduced cycle of $Q_0$, as defined in [BV07, Ch. 6]. Note that $N_n$ can be found as a subset of the coset representatives of $\text{SL}_2(\mathbb{Z}) \setminus \{ \det \gamma = n \}$, which we can choose to be

$$\left( \begin{array}{c} n/m \; j \; m \end{array} \right), \quad m|n, \; 0 \leq j \leq m - 1, \; (m, n/m) = 1.$$

The sets $M(n, A)$ and $M(d, A)$ for $d | n$ are not independent: if $Q \sim Q_0^n$ for some $\gamma_n \in N_n$, then we can find corresponding elements $\gamma_d$ and $\gamma_{n/d}$ such that $\gamma_n = \gamma_d \gamma_{n/d}$, and so we can generate it in $M(n, A)$ by applying suitable Hecke matrices to pairs in $M(d, A)$. This gives a recursive algorithm for computing $M(n, A)$, described in Algorithm 1.

It is convenient to work with so-called odd indicator functions on $\text{Cl}^+$, meaning functions of the form

$$\text{I}_A^*(B) := \text{I}_A(B) - \text{I}_A[\sqrt{D}](B) = \begin{cases} 1 & \text{if} \; B = A, \\ -1 & \text{if} \; B = A[\sqrt{D}], \\ 0 & \text{otherwise}. \end{cases}$$

We can pass between odd characters and odd indicator functions via the change of basis formulae

$$\psi(A) = \frac{1}{2} \sum_{B \in \text{Cl}^+} \psi(B) \text{I}_B^*(A) \quad \text{and} \quad \text{I}_A^*(B) = \frac{2}{h^+} \sum_{\psi \text{ odd}} \psi(B) \bar{\psi}(A).$$

These are simple consequences of the orthogonality relations for characters, see [Ser77, §2.3]. By linearity, we obtain the following version of Proposition 2.4.

Corollary 2.5. Fix an indefinite quadratic form $Q$ corresponding to a class $A \in \text{Cl}^+$. The series $\partial f_Q^+(q) = \log_p(u_A) + \sum_{n=1}^{\infty} a_n(\partial f_Q^+)$, where

$$a_n(\partial f_Q^+) = \sum_{n=1}^{\infty} \left( \sum_{(Q, \gamma) \in A(n, A)} \log_p \left( \frac{-b + n\sqrt{D}}{2a} \right) - \sum_{(Q, \gamma) \in M(n, A[\sqrt{D}])} \log_p \left( \frac{-b + n\sqrt{D}}{2a} \right) \right) q^n,$$

defines an $r$-overconvergent modular form of weight 2 and tame level 1 for any $r < p/(p+1)$. 

\section*{Algorithm 1:} Compute the set \( M(n,A) \) of nearly reduced forms.

\textbf{Input:}
\begin{itemize}
  \item A fundamental discriminant \( D \),
  \item A class \( A \) in \( \text{Cl}^+ \) represented by a reduced quadratic form \( Q_0 \),
  \item A positive integer \( n \).
\end{itemize}

\textbf{Output:} A set of sets \( \{M(d,A)\} \) indexed by divisors \( d \mid n \).

\begin{algorithm}
\begin{algorithmic}
  \State\textbf{if} \( n = 1 \) \textbf{then}
  \State \quad \textbf{return} \( \{(Q,1)\} \) \hfill \text{// Initialise \( M_n \)}
  \State \( M_n \leftarrow \emptyset \)
  \State \( p \leftarrow \text{smallest prime dividing } n \)
  \State \( d \leftarrow n/p \)
  \State \( M_d \leftarrow M(d,A) \)
  \State \( H_p \leftarrow \left\{ \left( \frac{p/m}{j} \right) m \in \{1,p\}, \ 0 \leq j \leq m - 1 \right\} \)
  \For{\( (Q_d,\gamma_d) \in M_d \)}
  \For{\( \delta \in H_p \)}
  \State \( Q' \leftarrow Q^\delta_d \)
  \If{\( Q' \not\in \text{SL}_2(\mathbb{Z})Q \) for all \( (Q,\gamma) \in M_n \)}
  \State \( Q_1,\ldots,Q_c \leftarrow \text{ReducedCycle}(Q') \)
  \State \( M_n \leftarrow M_n \cup \{(Q_1,\delta\gamma_m)\ldots,(Q_c,\delta\gamma_m)\} \)
  \EndIf
  \EndFor
  \EndFor
  \State \textbf{return} \( \{M_d : d \mid n\} \)
\end{algorithmic}
\end{algorithm}

\textbf{Proof.} Define \( \partial f_{Q}^+(q) := \frac{2}{h^+} \sum_{\psi \text{ odd}} \bar{\psi}(A)\partial f_{Q}^+(q) \), which has the effect of replacing \( \psi(a) \) in Equation \((2.6)\) with \( 1_A([a]) \). Being a linear combination of overconvergent modular forms, it is itself overconvergent of the same weight, level and rate of overconvergence.

Using Proposition \( 2.4 \), we can rewrite the series in terms of \( M(n,A) \) and \( M(n,A[\sqrt{D}]) \), showing that Equation \((2.21)\) holds for the non-constant terms. To compute the constant term of \( \partial f_{Q}^+(q) \), note that formally, \( u_\psi = \sum_{A \in \text{Cl}^+} \bar{\psi}(A) \cdot u_A \), so
\begin{equation}
\frac{2}{h^+} \sum_{\psi \text{ odd}} \bar{\psi}(A) \cdot u_\psi = \sum_{A \in \text{Cl}^+} \frac{2}{h^+} \sum_{\psi \text{ odd}} \bar{\psi}(A) \psi(A) \cdot u_A = \sum_{A \in \text{Cl}^+} 1_A \cdot u_A = u_A \cdot u_{A[\sqrt{D}]}^{-1}. \label{eq:constant}
\end{equation}

The condition \( \bar{u}_A = 1/u_A \) is equivalent to \( u_{A[\sqrt{D}]} = u_A^{-1} \), so \( \frac{2}{h^+} \sum_{\psi \text{ odd}} \frac{1}{2} \log_p \bar{\psi} = \log_p(u_A) \).

\begin{algorithm}
\end{algorithm}

This gives a reasonably efficient algorithm for computing \( \log_p u_A \), described in algorithm \( 2 \). The step \texttt{KatzBasis} is described in step 3 of \texttt{Lau11} Algorithm 1. Roughly speaking, a Katz basis form is the ratio of a classical modular form of weight \( 2 + (p-1)i \) and \( E_{p-1} \). Computing finitely many of these to sufficiently high finite precision, these span a subspace of \( M_2^+(\text{SL}_2(\mathbb{Z})) \) in which we can uniquely detect \( \partial f_{Q}^+ \). Further details and proofs can be found in \texttt{Kat73} Chap. 2.

The function \texttt{FindConstTerm} first solves a linear system obtained by solving for the higher order coefficients of \( \partial f_{Q}^+ \) in terms of those in \( B \), so that the constant
Here FindInSpaceOrdinaryProjection ordinary projection. We denote this step by $2$ matrix to the power $U$. Since this approximate basis is finite, the matrix can be computed to precision $\dim U$. To compute the ordinary projection, we use a trick due to Lauder. The idea is to always be found in the Katz basis from [Lau11 Algorithm 1], although in practice smaller values of $m$ are often sufficient.

With a little extra work we can compute the spectral expansion of $e_{\ord}(\partial f_Q^+)$.

The number of terms $m$ computed in the $q$-expansion of $\partial f_Q^+$ ensures that it can always be found in the Katz basis from [Lau11 Algorithm 1], although in practice smaller values of $m$ are often sufficient.

To compute the ordinary projection, we use a trick due to Lauder. The idea is to compute a matrix for the $U_p$-operator acting on the Katz basis $B$ from Algorithm 2 computed to precision $\dim M_{k'}(\SL_2(\mathbb{Z}))$, where $k' := 2 + (p - 1)\lfloor N(p + 1)/p \rfloor$. Since this approximate basis is finite, the matrix $U_p$ has finite rank. Raising the matrix to the power $2m$ and applying to the vector defining $\partial f_Q^+$ then gives the ordinary projection. We denote this step by $\OrdinateyProjection$ in Algorithm 3. Here $\FindInSpace(G, M)$ solves for $G = e_{\ord}(\partial f_Q^+)$ in terms of the eigenbasis for $M_2(\SL_2(\mathbb{Z}))$.

Algorithm 2: Algorithm for computing $\log_p u_A$.  

**Input:** A real quadratic field $F = \mathbb{Q}(\sqrt{D})$, a rational prime $p$ inert in $F$, a class $A \in \Cl^+$ represented by a reduced quadratic form $Q_0$, and an integer $N$.  

**Output:** $\log_p u_A$ as an element of $F_p$, to $p$-adic precision $N$.

\[
m \leftarrow p \cdot N \\
\text{Compute } \{M(n, A)\}_{n \leq m} \text{ using Algorithm 1} \\
\text{Compute } \{a_n(\partial f_Q^+)\}_{n \leq m} \text{ using Equation (2.21)} \\
B \leftarrow \text{KatzBasis}(M_{k'}(\SL_2(\mathbb{Z}))) \mod p^N, q^m) \\
\log_p u_A \leftarrow \text{FindConstTerm}(\{a_n\}_{n \leq m}, B) \\
\text{return } \log_p u_A \mod p^N
\]

Algorithm 3: Algorithm for the spectral expansion of $e_{\ord}(\partial f_Q^+)$.  

**Input:** A real quadratic field $F = \mathbb{Q}(\sqrt{D})$, a rational prime $p$ inert in $F$, a character $\psi: \Cl^+ \rightarrow \mathbb{C}^*$ and a positive integer $m$.  

**Output:** The coefficients $\lambda_0$ and $\lambda_f$ of $e_{\ord}(\partial f_Q^+)$ as elements of $F_p$, represented with $p$-adic precision $N$.

\[
m \leftarrow \dim M_{2+(p-1)\lfloor N(p+1)/p \rfloor}(\SL_2(\mathbb{Z})) \\
\text{Compute } B \mod (p^m, q^N) \text{ and } \{a_n(\partial f_Q^+)\}_{n=0}^N \text{ as in Algorithm 2} \\
G \leftarrow \OrdinateyProjection(\{a_n(\partial f_Q^+)\}_{n=0}^N, B) \\
M \leftarrow M_2(\Gamma_0(p)) \otimes F_p \\
\text{return } \FindInSpace(G, M)
\]

$M_2(\Gamma_0(p))$ and returns the corresponding coefficients, which are precisely $\lambda_0$ and the $\lambda_f$ for eigenforms $f$. The same algorithm works for $e_{\ord}(\partial f_Q^+)$.

3. From logarithms to invariants

In this section we explain how to recover $u_A$ from $\log_p u_A$ and $P_{\psi, f}$ from $\lambda_f$. 

}\
3.1. Recovering a Gross–Stark unit from its \( p \)-adic logarithm. The “virtual units” \( u_A \) are difficult to work with because they are formal powers of units in \( H \), and thus do not have a unique minimal polynomial. Instead, we use the Brumer–Stark conjecture and look instead for the (conjectural) element \( \epsilon_A \in \mathcal{O}_H^*[1/p] \) satisfying \( e \cdot u_A = \epsilon_A \otimes 1 \), where \( e := \#\mu(H) \). This property implies that \( \log_p u_A = \frac{1}{e} \log_p \epsilon_A \). Note that while \( u_A \) is determined uniquely by Equation \( (2.2) \) because \( \mathcal{O}_H^*[1/p] \otimes \mathbb{Q} \) is torsion-free, \( \epsilon_A \) is only unique up to roots of unity in \( H \).

This ambiguity is natural for several reasons. First, the Brumer–Stark conjecture and look instead for the (conjectural) element \( \epsilon_A \) because \( \mathcal{O}_H \) is only unique up to roots of unity in \( H \).

Second, \( \epsilon_A \) being defined only up to torsion in \( \mathcal{O}_H^*[1/p] \) mirrors the fact that Stark–Heegner points are defined up to torsion in \( E(H) \).

We can find the exact value of \( e \) without computing the unit group of \( \mathcal{O}_H \) directly by noting that any root of unity in \( H \) will lie in the genus field of \( F \), the largest subextension of \( H \) which is abelian over \( \mathbb{Q} \). This has the following classical description:

**Proposition 3.1 (\cite{Lem00} Prop. 2.19).** Let \( F = \mathbb{Q} (\sqrt{D}) \), and let \( D = D_1 \cdots D_t \) be the factorisation of \( D \) into prime discriminants, meaning each \( D_i \) is either \(-4, -8, 8\) or \((-1)^{(p-1)/2} p \) for an odd prime \( p \). Then the genus field of \( F \) equals \( \mathbb{Q} (\sqrt{D_1}, \ldots, \sqrt{D_t}) \).

Since the only quadratic extensions with other roots of unity than \( \pm 1 \) are \( \mathbb{Q} (\sqrt{-1}) \) and \( \mathbb{Q} (\sqrt{-3}) \), we obtain the following:

**Corollary 3.2.** We have \( \#\mu(H) > 2 \) if and only if either of the following holds:

1. \( D \equiv 0 \pmod{3} \), in which case \( H \) contains a cube root of unity.
2. \( D \equiv 0 \pmod{4} \) and \( D/4 \equiv 3 \pmod{4} \), in which case \( H \) contains \( \sqrt{-1} \).

The kernel of \( \log_p \) is much larger than that of the archimedean log, containing powers of \( p \) as well as roots of unity. Passing from \( \log_p \epsilon_A \) to \( \epsilon_A \) requires knowing both \( \text{ord}_p \epsilon_A \) and \( \epsilon_A \mod \mathfrak{P} \). We can deal with the latter by looping through all the roots of unity in \( H_p \), of which there are \( p^2 - 1 \), and test each product separately. This, along with the computation of the Katz basis, are the main bottlenecks in the algorithm for large values of \( p \). Certain Stark units modulo \( p \) appear in a recent conjecture of Harris–Venkatesh \cite{HVI19}, and it would be interesting to see if an analogous conjecture could describe the mod \( \mathfrak{P} \) reduction of \( u_A \).

To find the \( \mathfrak{P} \)-valuation, we use a classical theorem due to C. Meyer which we now describe. Let \( A \in \mathfrak{C}^+ \) be a narrow ideal class, and recall that the corresponding partial \( \zeta \)-function is given by

\[
\zeta(s, A) := \sum_{a \leq \mathcal{O}_F, [a] = A} \frac{1}{N(a)^s}, \quad \text{Re}(s) > 1.
\]

Let \( \zeta_-(s, A) := \frac{1}{2} \left( \zeta(s, A) - \zeta(s, A[(\sqrt{D})]) \right) \). This is non-zero if and only if \( F \) has no unit of negative norm, which is our running assumption.

Let \( \eta \) denote the fundamental unit of \( F \), by assumption satisfying \( N(\eta) = 1 \), and fix a representative \( a \leq \mathcal{O}_K \) for \( A \) with \( \mathbb{Z} \)-basis \( 1, w \). Then \( \eta \cdot a = a \), and so we can find integers \( a, b, c \) and \( d \) such that

\[
ecw = aw + b \quad \text{and} \quad \epsilon = cw + d.
\]
This is done explicitly in Algorithm 4. Since the action of \( \eta \) is invertible and preserves the order of the basis, the matrix \( \gamma_A := \begin{pmatrix} a & b \\ c & d \end{pmatrix} \) has determinant 1. Passing to the quadratic form \( Q = Q_1 x^2 + Q_2 xy + Q_3 y^2 \) associated to \( a \) by Proposition 2.3 and writing \( \eta = u + t \sqrt{D} \), a straightforward computation shows that

\[
\gamma_A = \begin{pmatrix} t + Q_2 u & 2Q_3 u \\ -2Q_1 u & t - Q_2 u \end{pmatrix}.
\]

Let \( \Phi: \text{SL}_2(\mathbb{Z}) \to \mathbb{R} \) denote the Dedekind symbol defined by

\[
\Phi \left( \begin{pmatrix} a & b \\ c & d \end{pmatrix} \right) := \begin{cases} b/d & \text{if } c = 0, \\ a + d - 12 \text{sgn}(c) \cdot s(a, c) & \text{if } c \neq 0, \end{cases}
\]

where \( s(a, c) \) is the Dedekind sum

\[
s(a, c) := \sum_{k=1}^{|c|} \left( \frac{ak}{c} \right) \left( \frac{k}{c} \right) \quad \text{for } (a, c) = 1, c \neq 0,
\]

with \((x)) = 0\) if \(x \in \mathbb{Z}\) and \((x)) = x - \lfloor x \rfloor - 1/2\) otherwise.

By adding a correction term to \( \Phi \), Rademacher showed that the eponymous Rademacher symbol,

\[
\Psi(\gamma) := \Phi(\gamma) - 3 \text{sgn}(c(a + d)),
\]

depends only on the conjugacy class of \( \gamma \).

**Theorem 3.3** (Meyer). Fix a class \( A \in \text{Cl}^+ \), and let \( \gamma_A \in \text{SL}_2(\mathbb{Z}) \) be the associated matrix. Then

\[
\zeta_{\gamma}(0, A) = \frac{1}{12} \Psi(\gamma_A).
\]

This follows from a version of Kronecker’s limit formula for real quadratic fields, and the proof is described in [DIT18].

**Corollary 3.4.** Let \( u_A \) be a Gross–Stark unit attached to a narrow ideal class \( A \). Then

\[
\text{ord}_P u_A = -\frac{1}{12} \Psi(\gamma_A).
\]

Similarly, for the associated Brumer–Stark unit \( \epsilon_A \),

\[
\text{ord}_P \epsilon_A = -\frac{e}{12} \Psi(\gamma_A),
\]

where \( e = \# \mu(H) \).

**Proof.** By Equation (2.2),

\[
\text{ord}_P u_A = \frac{1}{2} (\text{ord}_P u_A - \text{ord}_P u_{A[\sqrt{D}]}) = -\frac{1}{2} (\zeta(0, A) - \zeta(0, A[\sqrt{D}])) = -\zeta_{\gamma}(0, A) = -\frac{1}{12} \Psi(\gamma_A).
\]

The second claim follows immediately from the identity \( e \cdot u_A = \epsilon_A \otimes 1 \). \( \square \)
Algorithm 4: Compute ordₚ ϵₐ using Meyer’s formula.

**Input:** An indefinite binary quadratic form

\[ Q(x, y) = Q₁x^2 + Q₂xy + Q₃y^2 \]

of square-free discriminant \( D \), representing a narrow ideal class \( A \) of \( F = \mathbb{Q}(\sqrt{D}) \).

**Output:** ordₚ ϵₐ.

\[ t, u \leftarrow \text{PellSolution}(D) \quad // \text{Solve Pell’s equation in } \mathbb{Q}(\sqrt{D}) \text{ to find fundamental unit } \epsilon = u + t\sqrt{D}. \]

\[ \gammaₐ := \begin{pmatrix} a & b \\ c & d \end{pmatrix} \leftarrow \begin{pmatrix} t + Q₂u & 2Q₃u \\ -2Q₁u & t - Q₂u \end{pmatrix} \]

if \( c = 0 \) then

\[ \Phi \leftarrow b/d \]

else

\[ \Phi \leftarrow \frac{a+d}{c} - 12 \text{sgn}(c) \cdot \text{DedekindSum}(a, c) \]

\[ \Psi \leftarrow \Phi - 3 \text{sgn}(c(a + d)) \]

return \( -e \cdot \Psi/12 \)

Algorithm 4 describes how to efficiently compute ordₚ ϵₐ using Meyer’s theorem.

The fundamental solution of Pell’s equation grows very quickly as \( D \) gets large, so computing Dedekind sums by evaluating Equation (3.4) directly can be very slow for large values of \( D \). Instead we use a formula from [Apo90, Ex. 3.10]: By replacing \( c \) by \( -c \) and \( a \) by \( a \mod c \), we can assume that \( 0 < a < c \). Let \( r₀ := c, r₁ := a \) and define \( r_j \) recursively to be the remainders in the Euclidean algorithm applied to \( a \) and \( c \), satisfying \( r_{j+1} \equiv r_{j-1} \mod r_j \) and \( 1 = r_{n+1} < \ldots < r_{j+1} < r_j \ldots < r₀ \) for all \( 1 \leq j \leq n + 1 \). Then

\[
(3.10) \quad s(a, c) = \frac{1}{12} \sum_{j=1}^{n+1} \left( \frac{r_j^2 + r_{j-1}^2 + 1}{r_j r_{j-1}} \right) - \frac{(-1)^n + 1}{8}.
\]

This is very efficient in practice.

**Remark 3.5.** It is also possible to compute the value of \( \zeta_{-}(0, A) \) using a theorem due to Zagier, [Zag81 §14, Satz 2], which expresses \( \zeta_{-}(0, A) \) as an elementary sum of numbers appearing in the reduction algorithm for indefinite quadratic forms. We thank an anonymous referee for pointing this out. Having implemented both Zagier reduction and Algorithm 4 in the sage library, we see that Zagier’s formula is much faster in practice. However, if we compute the automorph using reduction theory instead of by solving Pell’s equation, then the algorithms perform roughly equally well.

By the minimal polynomial of \( \epsilon \) we mean the irreducible polynomial \( P \) of minimal degree satisfying \( P(\epsilon) = 0 \) with coefficients in \( \mathbb{O}_F \) not all divisible by the same prime, such that the leading term is a positive power of \( p \).

**Lemma 3.6.** Let \( \epsilon \) be a Brumer–Stark unit in \( \mathbb{O}_H[1/p] \times \), and let \( P(T) = \sum_{i=0}^{d} a_i T^i = a_d \prod_{\sigma \in G} (T - \sigma(\epsilon)) \) be its minimal polynomial. Then
(1) \( \epsilon \) is a primitive element of \( H \) over \( F \), \( H = F(\epsilon) \).

(2) \( P \) is of degree \( h^+ \), and after possibly twisting \( \epsilon \) by a root of unity in \( H \), has rational integer coefficients.

(3) \( P \) is reciprocal, \( a_i = a_{d-i} \) for all \( 0 \leq i \leq d \).

**Proof.** (i) We follow the strategy of [Rob97, Théorème 2.3]. Suppose \( \sigma(\epsilon) = \epsilon \) for some \( \sigma \in G \). For any character \( \chi : G \to \mathbb{C}^\times \), let \( L_s(\chi, \sigma) \) denote the \( L \)-function of \( \chi \) with the Euler factor at \( p = (p) \subset \mathcal{O}_F \) removed. Since \( \sigma_p = 1 \), \( \chi(\sigma_p) = 1 \), and so we have \( L_s(0, \chi) = 0 \). A consequence of the Brumer–Stark conjecture, see for example [Tat81] Prop. (5.5) and Conj. (4.2), is that \( \epsilon \) satisfies

\[
L'_S(0, \chi) = -\frac{1}{e} \sum_{\sigma' \in G} \chi(\sigma') \log |\sigma'(\epsilon)|_p
\]

for all \( \chi \). It follows that

\[
L'_S(0, \chi) = -\frac{1}{e} \sum_{\sigma' \in G} \chi(\sigma') \log |\sigma'(\epsilon)|_p
\]

\[
= -\frac{1}{e} \sum_{\sigma' \in G} \chi(\sigma') \log |\sigma'(\epsilon)|_p
\]

\[
= -\frac{\chi(\sigma)}{e} \sum_{\sigma'' \in G} \chi(\sigma'') \log |\sigma''(\epsilon)|_p
\]

\[
= \bar{\chi}(\sigma)L'_S(0, \chi).
\]

If \( \chi \) is odd, then \( L'_S(0, \chi) \neq 0 \) by [Gro81, Eq. 3.1], so \( \sigma \in \mathcal{I} \), and we can identify the image of the generator of \( \mathcal{G} \) with \( \sigma_p \).

By the Shimura reciprocity conjecture [DV21, Conj. 3.14], \( \sigma_p(J_{DR}[\tau]) = J_{DR}[\tau'] \). If we let \( \tau \) be the RM point corresponding to the identity class in \( \mathcal{I}^\times \), then \( J_{DR}[\tau] = J_{DR}[\tau'] \), and so \( J_{DR}[\tau] \) is fixed by \( \sigma_p \). Thus the minimal polynomial of \( J_{DR}[\tau] \) is fixed by \( \sigma_p \), and as \( \epsilon_A \) is a conjugate of \( J_{DR}[\tau] \) up to roots of unity in \( H \), the result follows.

(ii) The degree of \( P \) is \( h^+ \) since \( \epsilon \) is primitive. Let \( \tau \) be an RM-point in the sense of [DPV23]. As described in [DV21, §3.2], \( \text{Gal}(H/Q) \cong \text{Gal}(H/F) \times \text{Gal}(F/Q) \), and we can identify the image of the generator of \( \mathcal{G} \) with \( \sigma_p \).

Knowing the \( \mathcal{P} \)-valuations of all the conjugates of \( \epsilon \) lets us bound the valuations of the coefficients of \( P \):

**Lemma 3.7.** Let \( v_0, \ldots, v_{d/2-1} \) be the \( \mathcal{P} \)-valuations of the conjugates of \( \epsilon \) which are positive, ordered so that \( v_0 \geq v_1 \geq \ldots \geq v_{d/2-1} \geq 0 \), and \( v_{d/2} = 0 \). Then for any \( i = 0, \ldots, d/2 \) we have \( \text{ord}_p(a_i) \geq \sum_{j=0}^{d/2-i} v_{d/2-j} \). In particular, \( \text{ord}_p(a_d) = \text{ord}_p(a_0) = \sum_{j=0}^{d/2} v_j \).
Proof. By Lemma 3.6 (iii), the Newton polygon of $P$ is symmetric around the vertical line $x = d/2$, and its slopes are precisely equal to the $p$-valuations of the roots of $P$, the conjugates of $u$. Since $P$ is normalised, we know that $\text{ord}_p a_{d/2} = 0$, so the Newton polygon of $P$ intersects the $x$-axis at the point $(0, d/2)$. To estimate the remaining coefficients, note that the Newton polygon of $P$ will always lie in the convex hull of the polygon determined as follows: the boundary is symmetric around the line $x = d/2$, and is determined by the points $(i, \sum_{j=0}^{d/2-i} v_j)$ for $0 \leq i \leq d/2$. Since the $y$-coordinate of a point determining the Newton polygon of $P$ is the $\mathfrak{P}$-valuation of the corresponding coefficient, this gives the required inequality. □

Figure 1. The largest possible Newton polygon determined by the $\mathfrak{P}$-valuations of the conjugates of a Brumer–Stark unit over $\mathbb{Q}(\sqrt{469})$, where the vector of valuations is given by $(-3, -1, -1, 1, 1, 3)$.

Let $\alpha = (\alpha_1, \alpha_2) \in \mathbb{Z}/p^m \times \mathbb{Z}/p^m$ be an approximation of $\exp_p (\log_p \epsilon_A)$, where for a fixed generator $s$ of $\mathbb{Q}_p^2$ over $\mathbb{Q}_p$ we define the natural map

$$Z_{p^2} = \mathbb{Z}_p [s] \rightarrow \mathbb{Z}/p^m \times \mathbb{Z}/p^m \text{ by } a + bs \mapsto (a \mod p^m, b \mod p^m).$$

To find the minimal polynomial $P$ of $\alpha$, we apply the LLL algorithm to look for linear integral relations between powers of $\alpha$. This is a common application of the LLL algorithm, and a more detailed exposition can be found in [Coh93] §2.7.2. Roughly speaking, the LLL algorithm takes as input a basis $b_1, \ldots, b_d$ for a Euclidean lattice $\Lambda \subset \mathbb{R}^n$, and returns a “better” basis $b_1^*, \ldots, b_d^*$ for $\Lambda$, in the sense that $b_1^*$ has relatively small norm and that the vectors are approximately orthogonal. Let $v_0, \ldots, v_{d/2-1}$ be the $\mathfrak{P}$-valuations of the conjugates of $\epsilon$ ordered as in Lemma 3.7 computed using Algorithm 4. We want to find a short nontrivial vector in the lattice spanned by the rows of the following $(d/2 + 3) \times (d/2 + 3)$-matrix:

$$
\begin{pmatrix}
1 & 0 & \ldots & 0 & p^{v_0}(1 + \alpha_{d/2})_1 & p^{v_0}(1 + \alpha_{d/2})_2 \\
0 & 1 & \ldots & 0 & p^{v_1}(\alpha_1 + \alpha_{d-1})_1 & p^{v_1}(\alpha_1 + \alpha_{d-1})_2 \\
0 & 0 & \ldots & 0 & p^{v_2}(\alpha_2 + \alpha_{d-2})_1 & p^{v_2}(\alpha_2 + \alpha_{d-2})_2 \\
\vdots & \vdots & \ddots & \vdots & \vdots & \vdots \\
0 & 0 & \ldots & 1 & (\alpha_{d/2})_1 & (\alpha_{d/2})_2 \\
0 & 0 & \ldots & 0 & p^m & 0 \\
0 & 0 & \ldots & 0 & 0 & p^m
\end{pmatrix}
$$

(3.15)
A vector

$$w = \left( n_0, \ldots, n_{d/2}, n_{d/2}^{d/2} \alpha_{d/2}^{d/2} + \sum_{i=0}^{d/2-1} p^i n_i (\alpha_i + \alpha^{d-i} + p^m) \right)$$

in the lattice is small only if

$$n_{d/2}^{d/2} \alpha_{d/2}^{d/2} + \sum_{i=0}^{d/2-1} p^i n_i (\alpha_i + \alpha^{d-i} + p^m) \equiv 0 \mod p^m.$$ Then the polynomial

$$\sum_{i=0}^{d/2-1} p^i n_i x^i + \sum_{i=d/2+1}^{d} n_i x^i$$

is a good candidate for the minimal polynomial of $P$ over $\mathbb{Q}$. This suggests the following algorithm:

**Algorithm 5:** Find the minimal polynomial of $\epsilon_A$ from the $p$-adic approximation of $\log_p \epsilon_A$. 

**Input:**
- $\alpha \in \mathbb{Q}_p^2$ an approximation to $\exp_p (\log_p \epsilon_A)$,
- $v_0, \ldots, v_{d/2-1}$ as in Lemma 3.7.

**Output:** The minimal polynomial $P \in \mathbb{Z}[x]$ of $\epsilon_A$.

1. $\zeta \leftarrow$ primitive $(p^2 - 1)$-st root of unity in $\mathbb{Q}_p^2$
2. for $k = 0$ to $p^2 - 1$
   1. $\alpha' \leftarrow \zeta^k \alpha$
   2. $M \leftarrow$ matrix described in Equation (3.15) with $\alpha'$ in place of $\alpha$
   3. $v \leftarrow$ first vector returned by LLL$(M)$
   4. $P \leftarrow \sum_{i=0}^{d/2} n_i x^i + \sum_{i=d/2+1}^{d} n_d x^i$
   5. if $n_0 = p^r$ for some $r \in \mathbb{N}$ then
      1. if IsBSUnitCharPoly$(P)$ then // Described below
       2. return $P$.
3. return 0.

In practice, it is convenient to pick $A \in \text{Cl}^+$ so that $\text{ord}_p \epsilon_A$ is as close to 0 as possible. A similar algorithm for recognising an algebraic number from a $p$-adic approximation is given in [GHK+06, §4.2].

The function IsBSUnitCharPoly performs a series of tests in order, and returns False if any test fails:

1. if $P$ is irreducible over $F$, hence generates an extension of $F$ of degree $h^+$,
2. if the absolute discriminant of $H' := F[x]/(P(x))$ is a power of $D$, which is equivalent to $H'/F$ being unramified at all finite places,
3. if $H'/F$ is abelian.

At this point we know that $H' \cong H$, but to ensure that $P$ is the minimal polynomial of a Brumer–Stark unit and not just any generator of $H$, we perform a further test:

4. test if the extension generated by $P(x^e)$ is a central extension.

If all of these tests are passed, then it is quite likely, although not absolutely certain, that the polynomial $P$ has a Brumer–Stark unit as a root. To be absolutely
certain, one should test if \( P(x^e) \) generates an abelian extension of \( F \), but this is computationally unfeasible when both \( h \) and \( e \) are large.

**Remark 3.8.** The requirement that the extension should be central was part of Stark’s original conjecture, see [Sta80 Conj. 1], and in [PRS11 p. 40] Stark notes that this was sufficient for the factorisation of regulators which motivated it. The condition that the extension should be in fact be abelian was observed by Tate, leading to the formulation of the Brumer–Stark conjecture. This is now known to be true, by the work of Dasgupta and Kakde [DK23]. It would be interesting to know whether “central implies abelian” in this situation, that is: if \( \alpha \) is a \( p \)-unit which generates \( H \) with \( \mathfrak{p}^e \)-valuations specified by Equation (3.8) and \( \sqrt[n]{\alpha} \) generates a central extension of \( F \), is the extension actually abelian?

To describe the test in (4), it is convenient to introduce some notation: Let \( K := H(\sqrt[n]{\Delta}) \) and \( G_e := \text{Gal}(K/H) \). By Kummer theory, \( G_e \cong \mathbb{Z}/e\mathbb{Z} \). In this case \( \Gamma := \text{Gal}(K/F) \) is a group extension of \( G_e \) and \( G \),

\[
(3.17) \quad 1 \to G_e \to \Gamma \to G \to 1.
\]

The following lemma gives a simple criterion for deciding whether \( \Gamma \) is a central extension, that is, if \( G_e \) lies in the centre of \( \Gamma \), without computing \( \Gamma \) directly:

**Lemma 3.9.** Let \( F \) be a number field, \( H/F \) a Galois extension containing all \( e \)-th roots of unity, and \( \alpha \in H^\times \). Define \( \chi_{\text{cyc}} : G := \text{Gal}(H/F) \to (\mathbb{Z}/e\mathbb{Z})^\times \) by \( \zeta_{\text{cyc}}(\sigma) = \sigma(\zeta) \) for any \( \zeta \in \mu_e(H) \). Then \( K := H(\sqrt[n]{\alpha})/F \) is a central extension if and only if for all \( \sigma \in G \) there exists some \( \beta \in H^\times \) such that \( \sigma(\alpha) = \alpha^{\chi_{\text{cyc}}(\sigma)}\beta^e \).

**Proof.** There is a natural action of \( G \) on \( G_e := \text{Gal}(K/H) \) by conjugation, \( \sigma \cdot g := \sigma g \sigma^{-1} \), which is well-defined precisely because \( G_e \) is abelian. The extension \( K/F \) is central if and only if the action is trivial. Let \( \Delta \) be a set of representatives of \( H^\times/(H^\times)^e \), and note that this admits a natural action of \( G \). The Kummer pairing ([Gra03 §I.6]) gives a \( G \)-equivariant isomorphism \( G_e \cong \text{Hom}(\Delta, \mu_e(K)) \). The action of \( G_e \) on the right-hand side is given by \( (\sigma \cdot f)(\alpha) = f(\sigma^{-1}(\alpha))^{\chi_{\text{cyc}}(\sigma)} \), where \( \chi_{\text{cyc}}(\sigma) \) is defined by \( \sigma \cdot \zeta_e = \zeta_{\text{cyc}}(\sigma) \cdot \zeta_e \). The action of \( G \) on \( G_e \) is trivial if and only if the action on \( \text{Hom}(\Delta, \mu_e) \) is trivial. Each element of this group is given by \( \psi_g : \delta \mapsto (\delta, g) := \frac{g\sqrt{\delta}}{\sqrt{\delta}} \) for some \( g \in G_e \), and so \( \Gamma \) is central if and only if \( (\sigma \cdot \psi_g)(\delta) = \psi_g(\delta) \) for all \( \delta \in \Delta \), \( g \in G_e \) and \( \sigma \in G \). Equivalently,

\[
(3.18) \quad \left( g \frac{\sqrt{\sigma^{-1}(\delta)}}{\sqrt{\sigma^{-1}(\delta)}} \right)^{\chi_{\text{cyc}}(\sigma)} = \frac{g \sqrt{\delta}}{\sqrt{\delta}} \quad \text{hence} \quad g \left( \sqrt[\sqrt[\bar{\alpha}]}{\alpha^{\chi_{\text{cyc}}(\sigma)}} \right) = \sqrt[\sqrt[\bar{\alpha}]}{\alpha^{\chi_{\text{cyc}}(\sigma)}} \frac{\sigma(\alpha)}{\alpha(\alpha)},
\]

where \( \alpha := \sigma^{-1}(\delta) \). This being true for all \( g \) is equivalent to \( \alpha^{\chi_{\text{cyc}}(\sigma)} \) being an \( e \)-th power for all \( \sigma \). Finally, note that \( G \) acts transitively on \( \Delta \), so it suffices to check the criterion for a single \( \alpha \).

This test can be implemented quite easily, and is mainly bottlenecked by the computation of \( \text{Gal}(H/F) \), at least when \( [H:F] \) is reasonably large.

**Remark 3.10.** A test for whether an extension is abelian is found in [Coh12 Algorithm 4.4.6]. In short, the Takagi existence theorem gives a bijection between abelian extensions \( K/F \) and certain Takagi subgroups of a ray class group \( \text{Cl}_m F \),
where \( m \) is a sufficiently large modulus. However, this is very slow when \( e \) and \( h \) are large, because it requires computing the ray class group of \( F \) of modulus equal to the relative discriminant of \( H(\sqrt{\alpha})/F \), which is relatively large.

### 3.2. Detecting Stark–Heegner points

Our method of finding Stark–Heegner points is much more primitive, because we don’t have an equivalent of the Brumer–Stark conjecture.

Let \( E/Q \) be an elliptic curve with split multiplicative reduction at \( p \). Recall from Theorem 2.2 that if \( E \) has associated eigenform \( f \in M_2(\Gamma_0(p)) \), then the corresponding spectral coefficient \( \lambda_f = -L_{\text{alg}}(1,f) \log_{E}(P_{\psi,f}) \) involves a point \( P_{\psi,f} \) conjecturally defined over \( H \). To find this, we make use of the Tate curve \( E_q \) isomorphic to \( E \), which is described explicitly with the formulae in [Sil09, §C.14].

From this we can find an explicit isomorphism \( F_p^\times/q\mathbb{Z} \cong E_q(F_p) \), where \( q \) is an element satisfying \( |q| < 1 \) generating a discrete subgroup. An approximation to \( \alpha := \exp_p(-\lambda_f/L_{\text{alg}}(1,f)) \) can then be mapped to a point on the Tate curve \( E_q(F_p) \).

Mapping further into \( E(F_p) \), we may compute using descent a generating set \( \{g\} \) for \( E(H) \) and attempt to write the image of \( \alpha \) as an integral combination of them. Since \( P_{\psi,f} \) is only defined up to torsion, it is reasonable to look for a dependence between the formal logarithms of \( \alpha \) and the generators \( \{g\} \). To ensure convergence of the corresponding power series, we replace \( \alpha \) by \( \alpha^{p^{-1}} \) and each \( g \) by \( (p-1)g \).

Then we look for an integer relation by applying the LLL-algorithm to a suitable lattice as in the previous section. Following the convention in pari/gp, we call this step \textit{lindep}.

In summary, we have Algorithm 6.

**Algorithm 6:** Find Stark–Heegner point \( P_{\psi,f} \) from \( \lambda_f \).

**Input:**
- A normalised eigenform \( f \) in \( M_2(\Gamma_0(p)) \) with Hecke field \( \mathbb{Q} \),
- an elliptic curve \( E \) with associated eigenform \( f \),
- \( \lambda_f \in (\mathbb{Z}/p^n\mathbb{Z})^2 \) an approximation to \( -L_{\text{alg}}(1,f) \log_{E}(P_{\psi,f}) \in F_p \).

**Output:** The point \( P_{\psi,f} \) on the elliptic curve \( E \)

\[
\begin{align*}
E_q &\leftarrow \text{TateCurve}(E) \quad \text{// Using formulae in [Sil09, §C.14]} \\
\phi &\leftarrow \text{Isomorphism}(F_p^\times/q\mathbb{Z}, E_q) \quad \text{// As in [Sil09, Thm. 14.1]} \\
\beta &\leftarrow \phi(-\lambda_f/L_{\text{alg}}(1,f)) \\
H &\leftarrow \text{NarrowHilbertClassField}(F) \\
E(H) &\leftarrow \text{MordellWeilGroup}(E/H) \\
L &\leftarrow \text{[log}_{E_q}((p-1)/\beta)] \\
\text{// Compute formal logarithms of non-torsion generators of } E(H): \\
\text{for } g \in \text{Generators}(E(H)) \text{ do} \\
\text{if } \text{Order}(g) == 0 \text{ then} \\
\text{L} &\leftarrow L \cup \{\text{log}_{E}((p-1)g)\} \\
(n_1, n_2) &\leftarrow \text{lindep}(L) \quad \text{// Find integer relation between formal logarithms using LLL.} \\
\text{return } \sum n_g \cdot g/n_1 \in E(H)
\end{align*}
\]
By linearity, the algorithm works equally well when $\lambda_f$ comes from $\partial f^+_\psi$, in which case the corresponding Stark–Heegner point is a weighted sum of points $P_{\psi,f}$.

The algebraic part of the $L$-value can be computed either directly in magma using the intrinsic LRatio, or by using the BSD formula and the invariants of $E$ since $L(s,f) = L(s,E)$, or even analytically by approximating $L(1,E)$ and computing the periods of $E$.

One limitation of Algorithm 6 is that computing $E(H)$ is very slow when $[H : \mathbb{Q}] > 4$. We hope to resolve this in the future by improving the algorithms for detecting polynomials from $p$-adic approximations to their roots.

In the table below we have computed the minimal polynomials of the $X$ and $Y$ coordinates of the Stark–Heegner points coming from $\partial f^+_\psi$ on the curve $E : y^2 + xy + y = x^3 - x^2 - x - 14$. This is a model for $X_0(17)$, for which we have $L_{\text{alg}}(1, f) = 1/4$, so $\lambda_f = -\frac{1}{4} \log E \psi_{\psi,f}$. Here $\psi$ denotes the genus character associated with $\mathbb{Q}(\sqrt{D})$: since all the fields $\mathbb{Q}(\sqrt{D})$ for $D < 100$ with no fundamental unit of negative norm such that $(\frac{D}{\mathbb{Q}}) = -1$ have narrow class number 2, there is a unique nontrivial character. This satisfies $\partial f^+_{\psi} = -\partial f^+_{\overline{\psi}}$, where $Q$ is a quadratic form with class corresponding to the inverse different in $\text{Cl}^+$. Note that this matches the table on p. 545 of [DPV21].

Table 2. Table of Stark–Heegner points on $E : y^2 + xy + y = x^3 - x^2 - x - 14$, for $D < 100$.

Given the data computed, it is natural to study the “horizontal properties” of Brumer–Stark units, meaning the behaviour of the $p$-units $\epsilon$ as elements of $\overline{\mathbb{Q}}$ as $D$ varies.

</table>

The coefficients of the polynomials are all of roughly the same magnitude, despite the strong conditions on the $p$-valuation of the constant terms. In particular, the logarithmic height of the middle coefficient is roughly $\text{ord}_p a_0$, which is easily computed in terms of $L$-values using Equation (2.2). A classical result of Schur says that the coefficients of cyclotomic polynomials can be arbitrarily large. It would be interesting to know whether the same holds for our polynomials, normalised to be monic. The largest value we find is $822.637$, across the tables for $p \in \{2, 3, 5, 7, 11\}$. Figure 2 shows the absolute value of the middle coefficient of the normalised polynomials against the discriminant for different $p$.

If we plot the roots of the minimal polynomials on the unit circle as $D$ varies, it is natural to ask how the Brumer–Stark units distribute. It is well-known that the set of Galois orbits of primitive $N$-th roots of unity becomes equidistributed with respect to the Haar measure as $N$ tends to infinity. One might expect a similar thing to hold for a sequence of Brumer–Stark units, as the size of the corresponding orbits tend to infinity. A weaker statement is that the Brumer–Stark units, for $p$ fixed, become dense in the unit circle as $D \to \infty$.

Questions like these will be addressed in the author’s forthcoming DPhil thesis.
